## 「學位論文口試委員會審定書」掃描檔

審定書填寫方式以系所規定為準，但檢附在電子論文內的掃描檔須具備以下條件：

1. 含指導教授、口試委員及系所主管的完整簽名。
2. 口試委員人數正確，碩士口試委員至少 3 人、博士口試委員至少 5 人。
3. 若此頁有論文題目，題目應和書背、封面、書名頁、摘要頁的題目相符。
4. 此頁有無浮水印皆可。

# Abstract

Keyword: IoT Security, Information Security, Anomaly Detection, Multilayer Perceptron, Semantic Vector

As network environments become increasingly complex and dynamic, traditional intrusion detection methods struggle to keep pace with evolving threats and high-volume traffic. This paper proposes an efficient anomaly detection framework that leverages hash-based token embedding and a lightweight multi-layer perceptron (MLP) for the semantic representation of network flows. By transforming feature values into semantic tokens and utilizing a hashing trick for embedding lookup, our approach enables scalable and robust processing without maintaining an explicit vocabulary. The resulting embedding vectors are flattened and processed by the MLP to produce semantic vectors, which are clustered using a center loss strategy for unsupervised anomaly detection. Experimental results on public benchmark datasets demonstrate that our method achieves competitive accuracy with significantly improved computational efficiency compared to traditional attention-based models.

# Chapter 1 Introduction

Driven by the rapid advancement of digital transformation and smart infrastructure, the **Internet of Things (IoT)** has emerged as a cornerstone of next-generation information technology. Through the integration of sensors, embedded devices, communication modules, and platform software, IoT enables physical objects to communicate in real time and generate massive volumes of data. These data streams support a broad range of applications, such as smart manufacturing, intelligent transportation, remote healthcare, and smart homes, yielding substantial economic and societal value [1].

However, as the number of connected devices increases and deployment scenarios become more complex, IoT systems face unprecedented cybersecurity challenges. Many IoT devices are resource-constrained, infrequently updated, and difficult for users to manage. With limited encryption and a lack of monitoring mechanisms, these devices become prime targets for cyber intrusions and attacks. Effectively identifying abnormal behaviors and hidden threats in IoT network traffic has therefore become a pressing research priority.

Furthermore, existing intrusion detection technologies often struggle to adapt to evolving threats. While deep learning approaches such as Word2Vec and Transformer-based models [2] have demonstrated semantic learning capabilities, they also introduce critical drawbacks: large vocabulary requirements, high computational complexity, and limited flexibility in dynamic or resource-constrained environments.

To address these limitations, we propose **S2GE-NIDS** (Structured Semantics and Generation Embedded Network Intrusion Detection System) a lightweight, interpretable anomaly detection framework designed for IoT environments. S2GE-NIDS combines hash-based token embedding with a multi-layer perceptron (MLP) model and introduces a linked-list mechanism to mitigate hash collisions inherent to non-cryptographic hash functions such as MurmurHash3 [3]. This design enables efficient feature encoding while avoiding the need to maintain a large vocabulary.

In our approach, network packets are first transformed into semantic tokens and encoded using hash-based indexing. The resulting embedding vectors are concatenated into a single, fixed-length semantic vector, which is processed by an MLP and projected near a learned semantic

center. Any significant deviation from this center measured by Mahalanobis distance is classified as a potential anomaly [4].

The proposed S2GE-NIDS framework offers several key advantages over conventional intrusion detection systems. First, it eliminates the need for manual feature engineering and vocabulary maintenance by using a hash-based embedding approach, where field-value pairs are directly encoded into semantic vectors without relying on predefined lookup tables. This design greatly simplifies the preprocessing pipeline and enhances scalability. Second, the model provides a mathematically interpretable anomaly scoring mechanism by integrating Mahalanobis distance, which quantifies how far a sample deviates from the learned distribution of normal behavior. This not only improves detection accuracy but also enables explainable results. Third, the system is lightweight and highly efficient, relying on simple MLP-based encoding instead of complex deep architectures, making it well-suited for deployment in real-time or resource-constrained environments such as edge devices in IoT networks. Lastly, its generalized tokenization strategy allows for wide applicability across diverse packet structures, further improving its adaptability and robustness in various network scenarios.

The structure of this paper is organized as follows. Chapter 2 provides the background knowledge related to S2GE-NIDS (Structured Semantics and Generation Embedded Network Intrusion Detection System). Chapter 3 presents the architecture and methodology of the proposed framework, detailing the design and each module. Chapter 4 describes the implementation setup and steps, Chapter 5 provides the experimental results. Finally, Chapter 6 concludes and outlines for future research.

## Chapter 2 Related Work

This section will introduce the relevant basic knowledge, including the existing IoT network intrusion detection methods, Tokenization, Hash Embedding, and Mahanobis Distance.

### 2.1 Network Intrusion Detection System in IoT

In recent years, the proliferation of Internet of Things (IoT) devices has led to an increased focus on developing effective network intrusion detection systems (NIDS) tailored to the specific characteristics of IoT environments. Various approaches have been proposed to address the challenges associated with high-volume, heterogeneous network traffic, constrained device capabilities, and evolving attack patterns.

For example, Kharoubi et al. [5] proposed NIDS-DL-CNN, a convolutional neural network (CNN)-based detection system designed for IoT security. By applying CNN layers to extract spatial features from traffic data, the model achieved high classification performance on datasets such as CICIOT2023 and CICIOMT2024. The authors demonstrated that their method achieved excellent precision and recall in both binary and multi-class scenarios. However, a notable limitation of the CNN-based approach lies in its inability to fully capture temporal dependencies across packet sequences, while its reliance on supervised learning requires extensive labeled datasets.

Ashraf et al. [6] introduced a real-time intrusion detection system based on traditional machine learning classifiers applied to the BoT-IoT dataset. The study compared seven algorithms, including Random Forest, Artificial Neural Networks (ANN), and Support Vector Machines et al. Their results showed that Random Forest and ANN achieved the highest accuracy and robustness among all tested classifiers. Despite its efficiency, the NIDS system was highly dependent on manual feature engineering and lacked adaptability to novel threats, which are critical in fast-evolving IoT environments. Their work demonstrated that feature selection has a critical impact on the accuracy and efficiency of NIDS, especially when dealing with large datasets or new types of attacks.

Thaseen and Kumar [7] proposed a method combining feature selection with multi-class

SVM to improve the accuracy of NIDS. They demonstrated that a good feature selection strategy can effectively reduce detection errors and improve classification efficiency.

Table 2.1 provides a consolidated overview of eight widely adopted features commonly utilized in anomaly detection across both academic research and industrial applications.

Table 2.1 Common Anomalous Features in IoT Network Traffic and Their Descriptions

Feature	Description
Destination Port [8]	Specific port targets (e.g., 22, 23, 80, 443) are often associated with attacks. Abnormal access to these ports may suggest behaviors such as scanning, DDoS, or brute-force intrusion.
Protocol Type [9]	Sudden increases in uncommon protocols (e.g., ICMP, UDP) may reveal attempts to exploit protocol vulnerabilities or bypass filters.
Duration / flow_duration [9]	Unusually short or excessively long session durations may be indicative of attacks such as probing or data exfiltration.
Packet Length [8]	Anomalies in packet size—whether fixed, too long, or too short—often reflect malicious traffic like botnet propagation or worms.
Source IP / Destination IP [10]	Repeated access from abnormal IP addresses, or sudden surges in novel IP sources, are indicative of scanning, spoofing, or DDoS activity.
Flow Bytes per Second [8]	Sharp fluctuations surges or drops in flow byte rate may suggest DoS attacks or unauthorized data transfer.
TCP Flags [11]	Unusual combinations (e.g., SYN, FIN, RST) can indicate stealth scans or TCP-based flooding.
Number of Connections [8]	A large number of new connections established by a single IP in a short time often reflects worm propagation or botnet coordination.

## 2.2 Tokenization Technique in IoT Application

Tokenization is the process of converting raw packet data or traffic feature fields into semantically meaningful token sequences, thereby enabling anomaly detection models to perform contextual understanding and analysis. This technique facilitates the modeling of complex patterns in network traffic by translating low-level features into high-level representations.

Shapira et al. [12] proposed Flow2Vec, a framework that transforms network flow events into token sequences and applies contextual embeddings for analysis. This method is particularly effective for the classification and anomaly detection of encrypted traffic, as it captures semantic

relationships among protocols, IP addresses, and packet sizes.

Similarly, Li, Liu, and Wang [13] transformed URL paths and DNS queries in IoT traffic into text sequences. They performed n-gram segmentation followed by TF-IDF or Word2Vec embedding, and combined these representations with SVM and Random Forest classifiers to detect malicious domains.

Karim et al. [14] introduced a technique that tokenizes IoT network traffic features—such as protocols, port numbers, and flag bits—and processes them through an embedding layer followed by a Long Short-Term Memory (LSTM) network for semantic modeling. This approach demonstrated high classification accuracy and recall in identifying IoT malware samples.

Building on this idea, Muhammad et al. [15] proposed a lightweight method that combines token embedding with a deep classification model. Their technique tokenizes and standardizes packet fields such as timestamps, lengths, and protocol names, yielding significant improvements in real-time classification performance and anomaly detection—especially in resource-constrained IoT environments.

Javaid et al. [16] employed both one-hot encoding and word embedding for categorical features such as protocol types and flag statuses in IoT networks. These representations were input into deep neural networks to detect abnormal traffic. Experimental results demonstrated that embedding semantic information not only improves detection accuracy but also enhances generalization while reducing feature dimensionality.

Collectively, these studies confirm that tokenization strategies are highly effective in the context of IoT anomaly detection. By transforming heterogeneous traffic attributes into unified embedding vectors, such approaches enable models to learn and infer behavioral patterns across both packet-level and application-level traffic. This has significant implications for the scalability and accuracy of intrusion detection systems deployed in diverse and dynamic IoT environments.

Table 2.2 shows the comparison of some features in anomaly detection using Tokenization. For example, Protocol = TCP only retains the field name and value, and directly discards other symbols and spaces.

Table 2.2 Examples of Field-Value Tokenization in IoT Network Traffic

Feature Field	Tokenized Representation
Protocol = TCP	Protocol:TCP
Destination Port = 443	DstPort:443
Source IP = 192.168.0.1	SrcIP:192.168.0.1
Flow Duration = 120000	FlowDuration:120000
Payload Bytes = 56	PayloadBytes:56
Packet Count = 10	PacketCount:10
Flag = ACK	Flag:ACK
Destination IP = 10.0.0.5	DstIP:10.0.0.5

## 2.3 Hash Embedding in Anomaly Detection

Hash embedding is a commonly used lightweight feature encoding technique [17], particularly suitable for structured, high-dimensional, or large-category network data. Its core approach is to convert each field name, field value, or a combination of the two into a set of indices using a hash function (e.g., MurmurHash3), and then query an embedding table to obtain a fixed-length semantic vector. Typically, the (field name, field value) pair of each data sample is passed through a hash function such as MurmurHash3 to generate a set of row and column indices. These indices are then used to query a multi-dimensional embedding table, where a randomly initialized and trainable semantic vector is stored at each position [3].

Gupta et al. [18] proposed a hash embedding-based method for representing protocol-level IoT traffic, particularly focusing on categorical fields such as destination ports, device types, and payload signatures. Their approach utilized a multi-hash embedding layer before feeding the data into a shallow neural network for anomaly detection. Experiments on an IoT dataset demonstrated a 40% reduction in model size while retaining over 97% detection accuracy compared to one-hot encoding.

Building on this idea, Feng et al. [19] integrated hash embeddings into a lightweight convolutional architecture for edge-based IoT security. Their model encoded domain names, user-agent strings, and API patterns using two-way hash embeddings, which significantly reduced input dimensionality and inference latency. The system was capable of running on resource-constrained devices (e.g., Raspberry Pi), achieving an F1-score of 96.5% on the CIC-ToN-IoT dataset with an

average inference time of only 30 ms.

Overall, these studies confirm that hash embedding is a scalable and effective technique for representing sparse or categorical IoT traffic features, enabling fast and accurate detection of malicious behaviors under memory and computational constraints.

## 2.4 Multi-Layer Perceptron in Anomaly Detection

Multi-Layer Perceptrons (MLPs) have been widely applied in anomaly detection due to their capability to model non-linear relationships between input features and hidden patterns. Unlike traditional statistical models that rely on predefined thresholds or assumptions about data distribution, MLPs can learn complex, high-dimensional feature representations in a data-driven manner [20].

In recent years, MLP-based anomaly detection methods have been employed in various domains, including network security [21], industrial control systems [22], and IoT environments [23]. These models typically consist of multiple fully connected layers with nonlinear activation functions, such as ReLU or sigmoid, enabling the learning of hierarchical semantic features. The outputs are then used to distinguish between normal and abnormal behavior based on reconstruction error, classification scores, or learned distance metrics.

Moustafa and Slay [21] proposed a hybrid intrusion detection system combining feature selection and deep learning, utilizing an MLP as the final classifier. Experimental results demonstrated that this hybrid approach significantly outperforms classical machine learning algorithms such as decision trees and Naive Bayes, achieving over 95% detection accuracy and a low false positive rate, particularly excelling in identifying DoS and probe attacks.

Nguyen et al. [23] developed an anomaly detection method for IoT traffic using an autoencoder framework, with the decoder implemented as a multilayer perceptron (MLP). They focused on reducing communication overhead while maintaining detection accuracy, suitable for low-bandwidth IoT networks. The model takes raw traffic features (e.g., port numbers, packet sizes) and encodes them into a compact latent space before reconstructing them through a multi-layer MLP. Anomalies are identified based on high reconstruction error. Their experiments on the

BoT-IoT dataset showed that the MLP-based decoder could detect attacks such as DDoS and port scanning with an F1-score exceeding 98.5%, while maintaining a false positive rate below 1%, thus demonstrating the effectiveness of MLP in semantic compression and inference within constrained IoT devices.

Shone et al. [24] introduced a hybrid deep learning approach combining a stacked autoencoder with an MLP classifier to detect network intrusions. Their model was evaluated on the NSL-KDD dataset, achieving an accuracy of 85.42% and demonstrating superior performance over classical machine learning algorithms such as decision trees and support vector machines (SVM).

Similarly, Rahman et al. [25] applied a pure MLP-based architecture for anomaly detection on the BoT-IoT dataset. The network consisted of three hidden layers with ReLU activation and dropout regularization. The results showed that the MLP achieved over 98.5% detection accuracy and maintained a false positive rate below 1%, outperforming traditional algorithms such as k-nearest neighbors (KNN) and Naive Bayes.

Javaid et al. [16] further explored MLP in a deep learning pipeline tailored for IoT environments. They emphasized the importance of feature normalization and used a softmax output layer for multi-class classification. Their experiments on the KDDCup'99 and UNSW-NB15 datasets revealed that MLP models trained on optimized features could achieve both high recall and precision in detecting diverse attack types, including DoS, probing, and user-to-root exploits.

These findings suggest that MLPs can serve as a robust baseline model in IoT anomaly detection pipelines, particularly when combined with appropriate feature engineering and regularization techniques.

## 2.5 Semantic Vector in IoT Anomaly Detection

Semantic vector representations, originally popularized in natural language processing (NLP), have gained traction in anomaly detection tasks due to their ability to encode complex contextual information into fixed-length embeddings. In security-related applications, raw network traffic often contains heterogeneous features lacking explicit semantics; transforming these into seman-

tic vectors enables better generalization and interpretability [26].

Recent studies have applied semantic encoding strategies, such as Word2Vec and sequence embeddings, to convert protocol names, IP addresses, or header fields into high-dimensional vectors [13]. These semantic vectors capture latent relationships between fields and behaviors, allowing downstream models to detect subtle deviations from normal patterns. For instance, Shapira et al. [12] proposed Flow2Vec, which encodes sequences of network events into dense vectors, thereby improving anomaly detection in encrypted traffic.

Torres et al. [27] utilized a self-supervised Transformer model to learn semantic embeddings of packet sequences. They tokenized each field and value, converted them into word embeddings, and achieved anomaly classification accuracy exceeding 98% on the TON IoT dataset.

Rahman et al. [28] treated DNS and URL traffic as text sequences, constructed semantic vectors using n-gram segmentation and TF-IDF, and subsequently applied SVM and Random Forest classifiers, achieving an F1-score exceeding 96% in detecting malicious domains.

Nguyen et al. [29] concatenated the structured fields of IoT packets through semantic embedding and input them into an autoencoder model for reconstruction error analysis. The study highlighted that, compared to pure numerical encoding, semantic vectors can effectively improve anomaly recall and precision.

## 2.6 Mahanobis Distance in IoT Anomaly Detection

Mahalanobis distance was first proposed by the Indian statistician Prasanta Chandra Mahalanobis. It is a method to measure the "distance" between points and multidimensional statistical distributions, overcoming the limitations of the Euclidean distance, which cannot account for scale and correlation.

Venturini et al. [30] explored the application of Mahalanobis distance in smart home behavior analysis by using multidimensional time series to capture abnormal device usage scenarios. Their experiments showed that when the Mahalanobis distance exceeds a normal threshold, abnormal behaviors such as device failures or unexpected operations can be detected.

The classic formula is given as follows:

$$d_M(\mathbf{x}) = \sqrt{(\mathbf{x} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu})} \quad (2.1)$$

The equation  $d_M(\mathbf{x})$  denotes the Mahalanobis distance, where  $\mathbf{x}$  is the observation vector,  $\boldsymbol{\mu}$  is the mean vector, and  $\boldsymbol{\Sigma}$  is the covariance matrix of the distribution.

Another study examined the applicability of Mahalanobis Distance (MD) for detecting anomalies within IoT network traffic by integrating it with Principal Component Analysis (PCA) for dimensionality reduction [31]. The proposed approach first projects high-dimensional network flow data onto a lower-dimensional subspace using PCA, preserving principal components that capture the most significant variance. Subsequently, the deviation score of each data instance is computed using the Mahalanobis Distance relative to the center of normal traffic behavior. The evaluation demonstrated that MD exhibits superior detection performance compared to traditional distance metrics such as Euclidean distance.

Tharewal et al. [9] proposed an intrusion detection method combining Mahalanobis Distance and cluster analysis to analyze the network behavior patterns of IoT devices. They treated the multi-dimensional packet features as sample points, established a distribution model of normal behavior, and calculated the Mahalanobis Distance between test samples and the distribution center to identify anomalies. The results showed that this method effectively improves the detection rate while maintaining a low false positive rate.

Kwon et al. [32] proposed an anomaly detection method based on Mahalanobis Distance for resource-constrained IoT devices. The method calculates the distance between feature vectors and the normal behavior distribution locally on edge devices, thus avoiding cloud latency and reducing data leakage risks. Experiments demonstrated that this approach can quickly and accurately detect abnormal events in smart home and smart factory scenarios.

# Chapter 3 Methodology

In this section, we will introduce the S2GE-NIDS (structured semantics and generation embedded network intrusion detection system) architecture and detail its operational workflow, clearly delineating each step from semantic tokenization through anomaly detection and decision-making processes.

## 3.1 Architecture

The architecture of S2GE-NiDS is presented as Figure 3.1, including preprocess model, embedding model, and Mahalanobis model.

Figure 3.1 Architecture of S2GE-NIDS

The further description will begin in the section 3.1.1.

### 3.1.1 Preprocess Model

In the preprocessing phase, we will do the following process as data file selection and filtering, feature extraction, and tokenization. These steps are designed to transform raw network traffic into structured representations suitable for semantic embedding and anomaly detection.

#### 3.1.1.1 Classify and Clean Data

The first step in the preprocessing pipeline involves selecting and filtering data files to ensure their suitability for subsequent analysis. In this study, network traffic is collected and stored in the Comma-Separated Values (CSV) format, a widely adopted and flexible tabular data structure. CSV files are particularly well-suited for structured data representation due to their ease of parsing, compact storage, and seamless integration with mainstream data analysis libraries such as pandas and NumPy in Python.

After selecting the data format, the raw data are merged into a unified DataFrame and subjected to a series of cleaning procedures. First, all column names are normalized by removing extraneous whitespace and converting naming conventions where necessary to ensure consistency across feature dimensions. Next, column values containing missing or undefined entries are removed to prevent bias in downstream training. Finally, columns that contain only zeros are discarded.

During this stage, the resulting dataset serves as the foundation for the subsequent tokenization and embedding stages.

#### 3.1.1.2 Packet Semantic Extraction

Packet semantic extraction refers to the process of identifying and transforming raw packet-level attributes into semantically meaningful representations that facilitate accurate anomaly detection. As summarized in Table 2.1, a set of representative features—such as *Destination Port*, *Protocol Type*, *Flow Duration*, *Packet Length*, *Flow Bytes per Second*, *TCP Flag Counts*, and *Connection Count*—have been consistently validated in prior studies as effective indicators of anomalous or malicious traffic behavior.

### 3.1.1.3 Tokenization ID

Following the feature extraction phase, the structured network traffic attributes undergo a tokenization process, wherein categorical feature fields are transformed into discrete, semantically interpretable string tokens. These tokens form the foundation for subsequent vector embedding. The dataset comprises multiple structured records, each containing various categorical attributes—such as Destination Port, Protocol Type, and Source IP Address—that capture the behavioral characteristics of individual traffic flows. By converting these symbolic fields into tokenized string representations, the model preserves both the identity and contextual meaning of traffic patterns, thereby enabling more effective semantic encoding in later stages.

Table 3.1 shows the tokenization method employed, where each feature is transformed by concatenating its field name and corresponding value into a token. For example, "*DestinationPort:80*", "*FlowDuration:0.32817*", and "*ProtocolType:TCP*".

Table 3.1 Example of Tokenization

Field Name	Field Value	Token
Destination Port	80	DestinationPort:80
Flow Duration	0.32817	FlowDuration:0.32817
Protocol Type	TCP	ProtocolType:TCP

## 3.1.2 Embedding Model

To convert network packet features into vector representations that can be processed by the model, this architecture employs an efficient embedding model. The entire process includes Hash Embedding, flattening to a one-class vector, and using a multilayer perceptron (MLP) to obtain the final vector representation.

### 3.1.2.1 Hash Embedding

Hash embedding is a lightweight vectorization technique that utilizes non-cryptographic hashing to encode tokenized field-value pairs into fixed-size, trainable embeddings. In this study, we adopt the MurmurHash3 algorithm, an efficient and widely used hash function, to map each

token to a specific position in the embedding table. Its advantages include fast computation, uniform distribution, and language-independent implementation, making it well-suited for scalable anomaly detection in IoT environments.

To determine the target index for each token, we apply a modulo operation to the hash value using the smallest three-digit prime number, 233. This approach distributes tokens more evenly within the embedding space and reduces collision rates.

Figure 3.2 presents a representative subset of the embedding table used in our model, where each token derived from structured field-value pairs is mapped to an index through hashing and modulo operations.

In this process, both field names and their corresponding values are individually hashed using the MurmurHash3 function. The resulting integers are then projected into a fixed index range via modulo operation with a prime number  $P = 233$ , producing bounded coordinates in the embedding table. For instance, the field name `Destination_Port` yields an index of 129, while its value 80 maps to 166; these indices are used to locate specific embedding vectors.

Each vector is initialized randomly and refined during model training. The retrieved embeddings, such as the example 8-dimensional vector for indices (166, 129), capture semantic properties of the original tokens and are later concatenated as input to the MLP encoder for higher-level representation learning.

Figure 3.2 HashEmbedding Process

### 3.1.2.2 Flatten to One Class Vector

The flatten operation concatenates the tokenized embeddings from each column into a single vector for input to the next stage of the pipeline. Table 3.2 shows example embedding vectors for individual tokens, such as Destination Port 80 represented by [0.5012, 0.7061, 0.7705, 0.6871, 0.4636, 0.4809, 0.1913, 0.8319], Flow Duration 0.32817 represented by [0.227, 0.9268, 0.676, 0.9304, 0.5891, 0.3531, 0.2451, 0.9082], and Protocol TCP represented by [0.2309, 0.8674, 0.3565, 0.8259, 0.1846, 0.4375, 0.2524, 0.3008]. The final flattened vector is formed by concatenating these embeddings into a single vector: [0.5012, 0.7061, 0.7705, 0.6871, 0.4636, 0.4809, 0.1913, 0.8319, 0.227, 0.9268, 0.676, 0.9304, 0.5891, 0.3531, 0.2451, 0.9082, 0.2309, 0.8674, 0.3565, 0.8259, 0.1846, 0.4375, 0.2524, 0.3008].

Table 3.2 HashValue of Embedding Table Value

Token	Hash	Mod=223	Embedding Vector (16-d)
Destination_Port 80	1172070958	129	[0.5012, 0.7061, 0.7705, 0.6871, 0.4636, 0.4809, 0.1913, 0.8319]
	3167949985	166	
Flow_Duration 0.32817	2151518914	196	[0.227, 0.9268, 0.676, 0.9304, 0.5891, 0.3531, 0.2451, 0.9082]
	4143360759	20	
Protocol_Type TCP	56880774	164	[0.2309, 0.8674, 0.3565, 0.8259, 0.1846, 0.4375, 0.2524, 0.3008]
	3191464925	202	

### 3.1.2.3 MLP to Vector

To integrate the multiple field semantic vectors extracted from the embedding table for each packet into a unified semantic representation, a multi-layer perceptron (MLP) encoder module is introduced. The main task of this module is to map a flattened one-dimensional vector  $\mathbf{x} \in \mathbb{R}^{F \times d}$  to a fixed-dimensional semantic feature vector  $\mathbf{z} \in \mathbb{R}^k$ , where  $F$  is the number of fields,  $d$  is the embedding dimension of each field, and  $k$  is the dimension of the output vector.

## 3.1.3 Mahalanobis Distance Model

In the final stage of the S2GE-NIDS framework, a statistical distance-based method—**Mahalanobis Distance**—is applied to evaluate whether an observed semantic vector deviates significantly from the expected distribution of normal traffic. This metric is particularly effective for high-dimensional anomaly detection, as it accounts for feature correlations and variance [33].

### 3.1.3.1 Vector-to-Center Comparison

To enhance anomaly detection, S2GE-NIDS incorporates a center loss mechanism. During training, all semantic vectors corresponding to “normal” samples are aggregated to compute a center point  $c$ .

By accounting for the variability and correlation of each feature, the model is able to more accurately detect abnormal samples that are “off-center.”

$$D_M(z) = \sqrt{(z - c)^T \Sigma^{-1} (z - c)} \quad [34]$$

$z$  is the semantic vector of the input sample,  $c$  is the center vector of normal samples, and  $\Sigma^{-1}$  is the inverse of the covariance matrix of the training data’s embedding vectors.

### 3.1.3.2 Vector-to-Center Comparison

- The loss is defined as:

$$\mathcal{L} = \frac{1}{N} \sum_{i=1}^N \|z_i - c\|^2 = \frac{1}{N} \sum_{i=1}^N \sum_{j=1}^d (z_{ij} - c_j)^2 \quad [35]$$

$z_i \in \mathbb{R}^d$  is the embedding vector obtained after the  $i$ th input passes through the Semantic Encoder,  $c \in \mathbb{R}^d$  is the center point vector during training (center), and  $N$  is the total number of samples.

### 3.1.3.3 Determine the Anomaly Score

After obtaining the semantic vector  $\mathbf{z}$  of each input data point through the MLP encoder, and computing the center point  $\mathbf{c}$  based on all normal training samples, the system evaluates how far each sample deviates from the normal data distribution using the Mahalanobis distance metric.

The Mahalanobis distance score  $D_M(\mathbf{z})$ , as defined in Equation ??, quantifies the distance between a sample’s semantic representation  $\mathbf{z}$  and the center vector  $\mathbf{c}$ , while accounting for the variance and covariance of the embedding space. This distance serves as the anomaly score for each sample.

To determine whether a sample is anomalous, a threshold  $\tau$  is defined based on the distribution of distances observed in the training data. A sample is classified as anomalous if its Mahalanobis distance exceeds this threshold:

$$\text{Anomaly}(z) = \begin{cases} 1 & \text{if } D_M(z) > \tau \\ 0 & \text{otherwise} \end{cases} \quad [35]$$

Here,  $\tau$  can be determined in several ways, such as:

- Using the mean plus  $k$  standard deviations from the training distribution (e.g.,  $\tau = \mu + k\sigma$ ).
- Setting  $\tau$  based on a desired false-positive rate (e.g., the 95th percentile of  $D_M(z)$  on normal samples).

This threshold-based mechanism enables the system to make binary decisions (normal vs. anomalous) while preserving the interpretability and statistical grounding of the anomaly scores.

## 3.2 Flow

This section presents the proposed system, detailing its operational principles and experimental procedures. The complete workflow consists of three main components: the Preprocessing Model, the Embedding Model, and the Mahalanobis Distance module.

### 3.2.1 Preprocess Model

As shown in Figure 3.3, the system receives the uploaded network packet data and verifies whether its format conforms to the CSV (Comma-Separated Values) format. If the data format does not conform to CSV, the system takes no further action. In the subsequent stage, the system performs data cleaning, including the removal of missing values and special characters from the data packets.

Subsequently, specific fields related to common anomaly detection features are extracted, such as Destination Port, Protocol Type, and Source IP (SrcIP). These fields serve as important inputs for subsequent model analysis.

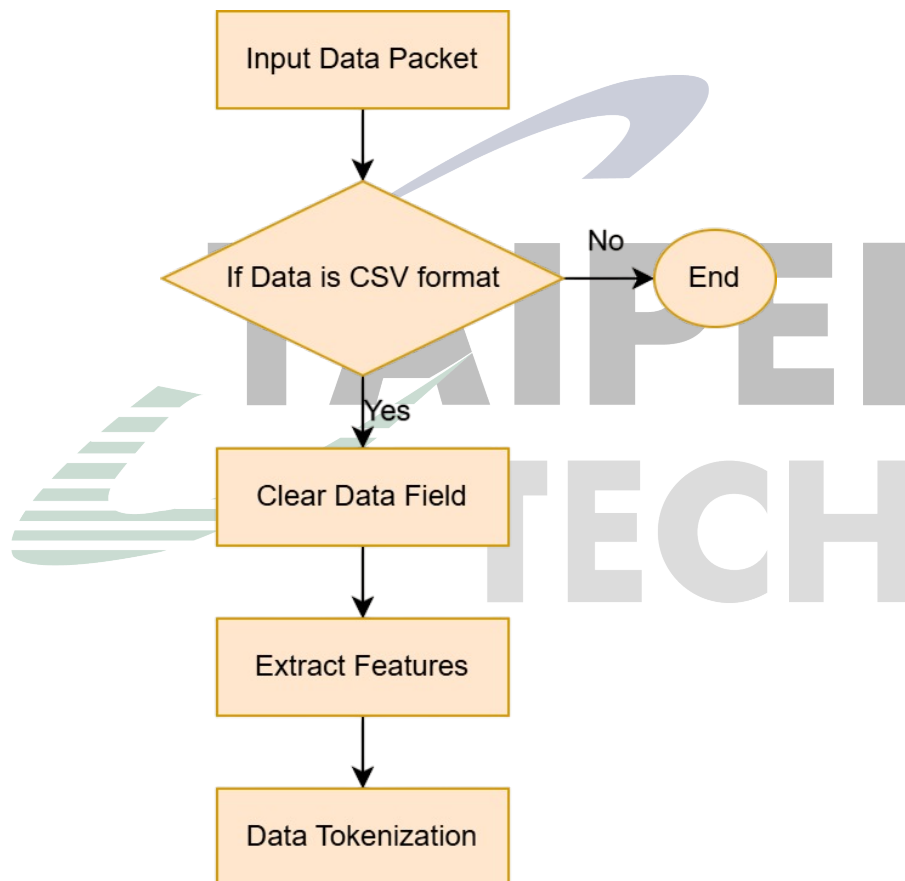

Figure 3.3 FlowChart for Preprocess Model

Finally, the field names and their respective values are combined into tokens—for example, Protocol\_TCP or Port\_80—and fed into a semantic embedding model to be transformed into vectors for further processing.

### 3.2.2 Implementation Procedure

This module is responsible for converting the structured semantic token sequence produced in the pre-processing stage into a fixed-dimensional numerical vector representation. This module is including Hash Embedding, Flatten to One Class Vector and MLP to Vector.

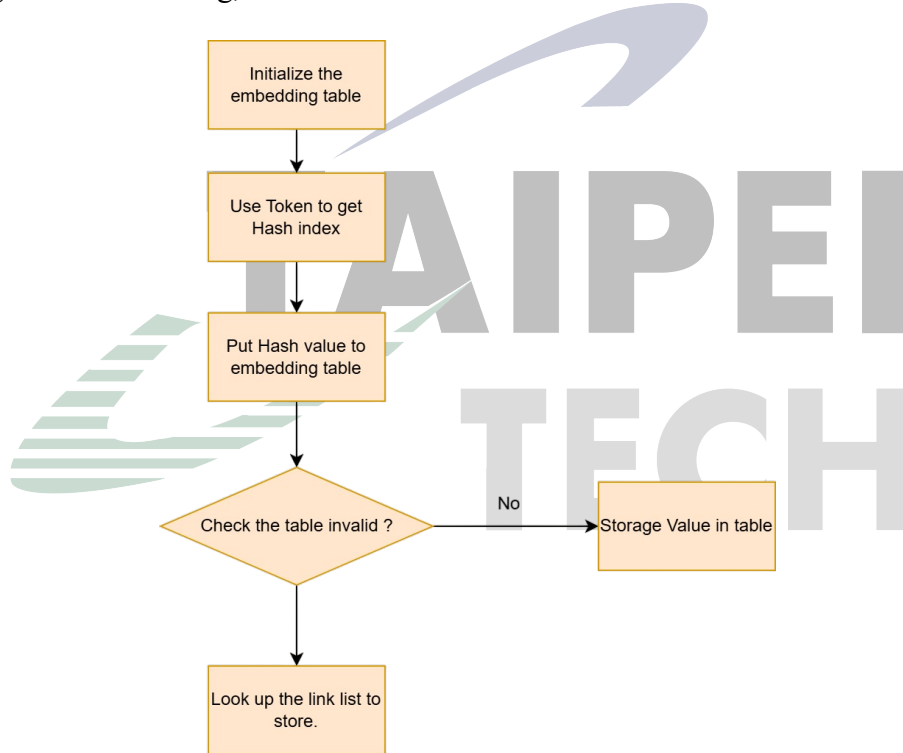

Figure 3.4 Hash Embedding for Embedding Model

Traditional one-hot or dictionary embedding methods require maintaining a vocabulary, which is inefficient for IoT packet data. Therefore, this study employs the non-cryptographic hash function MurmurHash3 to map each <field name>:<value> token to a trainable embedding position.

To map discrete feature tokens into a fixed-size embedding space without maintaining a pre-defined vocabulary, a dual-stage hash embedding strategy is utilized. Each token in the form of <FieldName>:<Value> is decomposed into two components: the field identifier and the associ-

ated value. Both components are independently processed by the MurmurHash3 function, which offers fast computation and near-uniform distribution.

Formally, for a given token  $t = \text{Field}:\text{Value}$ , we compute:

$$\text{row\_idx} = \text{MurmurHash3}(\text{Field}) \bmod P \quad (3.1)$$

$$\text{col\_idx} = \text{MurmurHash3}(\text{Value}) \bmod P \quad (3.2)$$

where  $P = 233$  is a small prime number chosen to reduce the probability of hash collisions and to ensure efficient modular indexing.

The resulting  $(\text{row\_idx}, \text{col\_idx})$  pair identifies a unique coordinate in the 2D embedding table  $\mathbf{E} \in \mathbb{R}^{P \times P \times d}$ , where each entry holds a trainable  $d$ -dimensional embedding vector.

### 3.2.3 Mahalanobis Distance Model

In this section, we present an anomaly detection method based on the Mahalanobis distance as the core model for decision making. The discussion is organized into three parts: Vector-to-Center Comparison, Vector-to-Center Distance Calculation, and Anomaly Score Determination.

Given  $N$  semantic vectors  $\mathbf{z}_1, \dots, \mathbf{z}_N$  generated from benign training data, we first compute the statistical mean (center) vector  $\mathbf{c}$  and covariance matrix  $\Sigma$ :

$$\mathbf{c} = \frac{1}{N} \sum_{i=1}^N \mathbf{z}_i \quad (3.3)$$

$$\Sigma = \frac{1}{N-1} \sum_{i=1}^N (\mathbf{z}_i - \mathbf{c})(\mathbf{z}_i - \mathbf{c})^T \quad (3.4)$$

For any test vector  $\mathbf{z}$ , the Mahalanobis distance  $D_M(\mathbf{z})$  from the normal distribution is calculated as:

$$D_M(\mathbf{z}) = \sqrt{(\mathbf{z} - \mathbf{c})^T \Sigma^{-1} (\mathbf{z} - \mathbf{c})} \quad (3.5)$$

A larger distance indicates a greater deviation from the normal behavior, suggesting a higher probability of being anomalous.

We define a threshold  $\tau$  based on the distribution of  $D_M(\cdot)$  in the training data (e.g., 95th percentile). A test vector  $\mathbf{z}$  is labeled as anomalous if its distance exceeds  $\tau$ :

$$\text{Anomaly}(\mathbf{z}) = \begin{cases} 1, & \text{if } D_M(\mathbf{z}) > \tau \\ 0, & \text{otherwise} \end{cases} \quad (3.6)$$

- **Input:** Semantic vector  $\mathbf{z} \in \mathbb{R}^k$  (from MLP)
- **Output:** Anomaly score  $D_M(\mathbf{z})$  and binary decision
- **Computation:** Based on  $\mathbf{c}$  and  $\Sigma$  estimated from training data
- **Unsupervised:** Requires only benign data for training
- **Interpretable:** Outputs a clear statistical distance as anomaly score
- **Statistically Sound:** Incorporates feature correlation via covariance
- **Efficient:** Only requires mean and covariance estimation once during training

# Chapter 4 Implementation

The experimental implementation of this study was conducted on the Windows 11 operating system. Visual Studio Code (VS Code) was utilized as the primary development environment, integrated with the Anaconda distribution for Python to manage package dependencies and virtual environments. A range of scientific computing and machine learning packages were installed to facilitate algorithm development, model training, and evaluation workflows. Detailed configuration steps and setup instructions are described in the following subsection.

## 4.1 Hardware Requirements

Table 4.1 provides detailed specifications and purposes of each hardware component utilized in our experimental environment.

Table 4.1 Hardware Requirements

Component	Specification
CPU	12th Gen Intel(R) Core(TM) i5-12500H @ 2.50 GHz
RAM	16.0 GB (15.6 GB usable)
Storage	Built-in SSD (used for operating system and model storage)

### 4.1.1 Software Requirements

This chapter mainly introduces the software installation process, which is divided into several steps. Table 4.2 lists the software used in our experimental setup, along with their purposes and license types.

#### Step 1: Installing Anaconda

Anaconda is an open-source Python platform designed for data science and machine learning development. It integrates commonly used data analysis libraries such as NumPy (numerical operations), Pandas (data processing), and Seaborn (data visualization).

**Install Anaconda** The installation began by double-clicking the downloaded Anaconda installer, followed by clicking “Next” to proceed to the next step (see Figure ??).

Table 4.2 Software and Libraries Used in the Experiment

Software/Library	Version	Purpose	License
Visual Studio Code [36]	1.89.1	A lightweight and extensible code editor used as the primary integrated development environment (IDE) for editing Python scripts and managing project structure.	MIT
Anaconda Prompt [37]	2024.02	A command-line interface provided by the Anaconda distribution, used for managing Python virtual environments and installing dependencies via Conda or pip.	BSD
Python [38]	3.9.18	The main programming language used to implement the core modules of the proposed system, including preprocessing, model training, and evaluation routines.	Python License
NumPy [39]	1.26.4	Provides high-performance array structures and functions for numerical computing, especially efficient vector and matrix operations.	BSD
Pandas [40]	2.2.2	Offers powerful data manipulation and analysis tools, including DataFrame structures used for preprocessing and filtering packet data.	BSD
Scikit-learn [41]	1.4.2	Provides a wide range of machine learning algorithms, particularly the Multi-Layer Perceptron (MLP) classifier used in this study.	BSD
mmh3 [42]	4.0.1	Implements MurmurHash3, a fast non-cryptographic hashing function used to convert tokens into integer values for embedding.	MIT
PyTorch [43]	2.2.2+cpu	A deep learning framework used to define and train neural networks, including custom embedding and classification models.	BSD

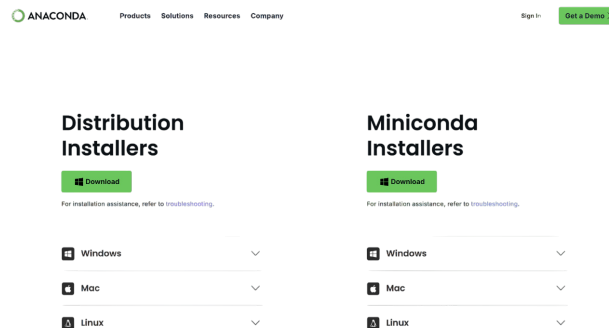

Figure 4.1 Download on Official Anaconda Website

When selecting the installation type, “Just Me” was chosen for personal use, then “Next” was clicked to continue.

Figure 4.2 Installation for Anaconda

In the installation options, it is recommended not to check the option to add Anaconda to the PATH environment variable (unless specifically required). Simply click “Install” to begin the installation process.

After the installation completes, Anaconda Navigator can be found and launched from the Windows Start menu (see Figure ??).

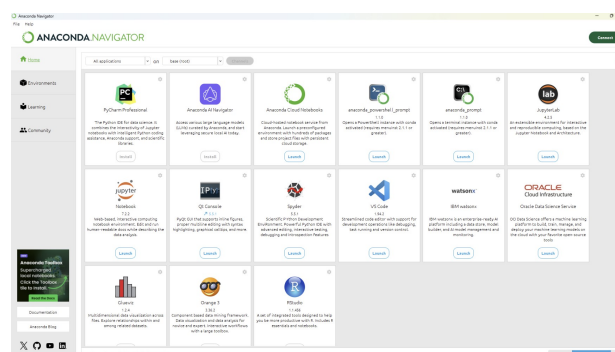

Figure 4.3 FlowChart for Preprocess Model

## Step 2: Installing Visual Studio Code

Visual Studio Code (VS Code) (see Figure ??) is a lightweight and extensible source code editor that, when used with the Python extension, provides enhanced development capabilities. The installation package can be downloaded from the official website.

## Step 3: Creating a Python Virtual Environment

Figure 4.4 Visual Studio Code User Interface

Use the Anaconda Prompt to create a virtual environment with the designated Python version:

```
conda create -n nids_env python=3.9
conda activate nids_env
```

#### Step 4: Installing Required Packages

The packages required in this study are listed below and can be installed using pip:

```
pip install numpy pandas scikit-learn matplotlib seaborn torch mmh3
```

A brief description of each package is provided in Table 4.2.

#### Step 5: Selecting the VS Code Interpreter

In Visual Studio Code, press `Ctrl+Shift+P` to open the command palette, then select *"Python: Select Interpreter"*. Choose the previously created `nids_env` virtual environment from the list of available interpreters.

### 4.1.2 Verifying the Installation

To verify the installation, create a file named `main.py` and include the following test code:

```
import numpy as np
import pandas as pd
import torch
import mmh3
print("All packages loaded successfully!")
```

Execute the script in the terminal with the following command:

```
python main.py
```

### 4.1.3 Dataset Description

This study utilizes the publicly available **CICIoT2023** dataset for experiments. The dataset contains normal and anomalous traffic packets from various IoT network devices, captured using Wireshark and converted into .csv format. In this study, three fields—**Destination Port**, **Protocol Type**, and **Source IP**—are selected as the primary input features for tokenization and embedding.

The training set consists of  $N = 15,000$  normal packet samples, while the test set includes  $M = 5,000$  anomalous samples and 3,000 normal samples. These are mixed for unsupervised anomaly detection evaluation.

If the message is displayed successfully, it indicates that the environment has been correctly set up.

We observed the distribution of Mahalanobis distances for normal packets and selected the 95th percentile of this distribution as the anomaly detection threshold  $\tau$ . This strategy is based on the statistical assumption that 5% of the additional samples may represent potential anomalies.

Furthermore, cross-validation with  $k = 5$  folds was employed by partitioning the training data. After each training, the center and distance distribution of normal samples were recalculated. The optimal percentile threshold, ranging from 93% to 96%, was determined based on the best F1-score of each fold. Ultimately, a fixed threshold of 95% was selected as the balance point.

## Chapter 5 Results

Table 5.1 Anomaly Detection Performance Comparison

Model	Precision	Recall	F1-Score	Time (ms/sample)
Isolation Forest	0.82	0.78	0.80	1.2
AutoEncoder	0.85	0.83	0.84	2.5
<b>S2GE-NIDS</b>	<b>0.86</b>	<b>0.90</b>	<b>0.88</b>	<b>0.8</b>
