Abstract

Keyword: IoT Security, Information Security, Anomaly Detection, Multilayer Perceptron, Semantic Vector
As network environments become increasingly complex and dynamic, traditional intrusion detection methods struggle to keep pace with evolving threats and high-volume traffic. This paper proposes an efficient anomaly detection framework that leverages hash-based token embedding and a lightweight multi-layer perceptron (MLP) for the semantic representation of network flows. By transforming feature values into semantic tokens and utilizing a hashing trick for embedding lookup, our approach enables scalable and robust processing without maintaining an explicit vocabulary. The resulting embedding vectors are flattened and processed by the MLP to produce semantic vectors, which are clustered using a center loss strategy for unsupervised anomaly detection. Experimental results on public benchmark datasets demonstrate that our method achieves competitive accuracy with significantly improved computational efficiency compared to traditional attention-based models.

Chapter 1 Introduction

Driven by the rapid advancement of digital transformation and smart infrastructure, the **Internet of Things (IoT)** has emerged as a cornerstone of next-generation information technology. Through the integration of sensors, embedded devices, communication modules, and platform software, IoT enables physical objects to communicate in real time and generate massive volumes of data. These data streams support a broad range of applications, such as smart manufacturing, intelligent transportation, remote healthcare, and smart homes, yielding substantial economic and societal value [1].

However, as the number of connected devices increases and deployment scenarios become more complex, IoT systems face unprecedented cybersecurity challenges. Many IoT devices are resource-constrained, infrequently updated, and difficult for users to manage. With limited encryption and a lack of monitoring mechanisms, these devices become prime targets for cyber intrusions and attacks. Effectively identifying abnormal behaviors and hidden threats in IoT network traffic has therefore become a pressing research priority.

Furthermore, existing intrusion detection technologies often struggle to adapt to evolving threats. While deep learning approaches such as Word2Vec and Transformer-based models [2] have demonstrated semantic learning capabilities, they also introduce critical drawbacks: large vocabulary requirements, high computational complexity, and limited flexibility in dynamic or resource-constrained environments.

To address these limitations, we propose **S2GE-NIDS** (Structured Semantics and Generation Embedded Network Intrusion Detection System) a lightweight, interpretable anomaly detection framework designed for IoT environments. S2GE-NIDS combines hash-based token embedding with a multi-layer perceptron (MLP) model and introduces a linked-list mechanism to mitigate hash collisions inherent to non-cryptographic hash functions such as MurmurHash3 [3]. This design enables efficient feature encoding while avoiding the need to maintain a large vocabulary.

In our approach, network packets are first transformed into semantic tokens and encoded using hash-based indexing. The resulting embedding vectors are concatenated into a single, fixed-length semantic vector, which is processed by an MLP and projected near a learned semantic

center. Any significant deviation from this center measured by Mahalanobis distance is classified as a potential anomaly [4].

The proposed S2GE-NIDS framework offers several key advantages over conventional intrusion detection systems. First, it eliminates the need for manual feature engineering and vocabulary maintenance by using a hash-based embedding approach, where field-value pairs are directly encoded into semantic vectors without relying on predefined lookup tables. This design greatly simplifies the preprocessing pipeline and enhances scalability. Second, the model provides a mathematically interpretable anomaly scoring mechanism by integrating Mahalanobis distance, which quantifies how far a sample deviates from the learned distribution of normal behavior. This not only improves detection accuracy but also enables explainable results. Third, the system is lightweight and highly efficient, relying on simple MLP-based encoding instead of complex deep architectures, making it well-suited for deployment in real-time or resource-constrained environments such as edge devices in IoT networks. Lastly, its generalized tokenization strategy allows for wide applicability across diverse packet structures, further improving its adaptability and robustness in various network scenarios.

The structure of this paper is organized as follows. Chapter 2 provides the background knowledge related to S2GE-NIDS (Structured Semantics and Generation Embedded Network Intrusion Detection System). Chapter 3 presents the architecture and methodology of the proposed framework, detailing the design and each module. Chapter 4 describes the implementation setup and steps, Chapter 5 provides the experimental results. Finally, Chapter 6 concludes and outlines for future research.

Chapter 2 Related Work

This section will introduce the relevant basic knowledge, including the existing the IoT network intrusion detection methods, Tokenization, Hash Embedding, and language tags.

2.1 Network Intrusion Detection System in IoT

In recent years, the proliferation of Internet of Things (IoT) devices has led to an increased focus on developing effective network intrusion detection systems (NIDS) tailored to the specific characteristics of IoT environments. Various approaches have been proposed to address the challenges associated with high-volume, heterogeneous network traffic, constrained device capabilities, and evolving attack patterns.

For example, Kharoubi et al. [5] proposed NIDS-DL-CNN, a convolutional neural network (CNN)-based detection system designed for IoT security. By applying CNN layers to extract spatial features from traffic data, the model achieved high classification performance on datasets such as CICIoT2023 and CICIoMT2024. The authors demonstrated that their method achieved excellent precision and recall in both binary and multi-class scenarios. However, a notable limitation of the CNN-based approach lies in its inability to fully capture temporal dependencies across packet sequences, and its reliance on supervised learning requires extensive labeled datasets.

Ashraf et al. [6] introduced a real-time intrusion detection system (NIDS) based on traditional machine learning classifiers applied to the BoT-IoT dataset. The study compared seven algorithms, including Random Forest, Artificial Neural Networks (ANN) et al., and Support Vector Machines. Their results showed that Random Forest and ANN achieved the highest accuracy and robustness among all tested classifiers. Despite its efficiency, the NIDS system was highly dependent on manual feature engineering and lacked adaptability to novel threats, which are critical in fast-evolving IoT environments.

Lee and Stolfo [7] proposed a method for extracting features from network traffic to build models that can effectively detect intrusions. They thus demonstrated that feature selection has a critical impact on the accuracy and efficiency of NIDS, especially when dealing with large datasets

or new types of attacks.

Thaseen, I. S., Kumar, C. A. [8] proposed a method combining feature selection with multi-class SVM to improve the accuracy of NIDS. They demonstrated that a good feature selection strategy can effectively reduce detection errors and improve classification efficiency.

Table 2.1 provides a consolidated overview of eight widely adopted features commonly utilized in anomaly detection across both academic research and industrial applications.

Table 2.1 Common Anomalous Features in IoT Network Traffic and Their Descriptions

Feature	Description
Destination Port [9]	Specific port targets (e.g., 22, 23, 80, 443) are often associated with attacks. Abnormal access to these ports may suggest behaviors such as scanning, DDoS, or brute-force intrusion.
Protocol Type [10]	Sudden increases in uncommon protocols (e.g., ICMP, UDP) may reveal attempts to exploit protocol vulnerabilities or bypass filters.
Duration / flow_duration [10]	Unusually short or excessively long session durations may be indicative of attacks such as probing or data exfiltration.
Packet Length [9]	Anomalies in packet size—whether fixed, too long, or too short—often reflect malicious traffic like botnet propagation or worms.
Source IP / Destination IP [11]	Repeated access from abnormal IP addresses, or sudden surges in novel IP sources, are indicative of scanning, spoofing, or DDoS activity.
Flow Bytes per Second [9]	Sharp fluctuations surges or drops in flow byte rate may suggest DoS attacks or unauthorized data transfer.
TCP Flags [12]	Unusual combinations (e.g., SYN, FIN, RST) can indicate stealth scans or TCP-based flooding.
Number of Connections [9]	A large number of new connections established by a single IP in a short time often reflects worm propagation or botnet coordination.

2.2   Tokenization Technique in IoT Application

Tokenization is the process of converting raw packet data or traffic feature fields into semantically meaningful token sequences, thereby enabling anomaly detection models to perform contextual understanding and analysis. This technique facilitates the modeling of complex patterns in network traffic by translating low-level features into high-level representations.

Shapira et al. [13] proposed Flow2Vec, a framework that transforms network flow events

into token sequences and applies contextual embeddings for analysis. This method is particularly effective for the classification and anomaly detection of encrypted traffic, as it captures the semantic relationships among protocols, IP addresses, and packet sizes. Similarly, Li, Liu, and Wang [14] transformed URL paths and DNS queries in IoT traffic into text sequences. They performed n-gram segmentation, followed by TF-IDF or Word2Vec embedding, and combined these representations with SVM and RandomForest classifiers to detect malicious domains.

Karim et al. [15] introduced a technique that tokenizes IoT network traffic features—such as protocols, port numbers, and flag bits—and processes them through an embedding layer followed by a Long Short-Term Memory (LSTM) network for semantic modeling. This approach demonstrated high classification accuracy and recall in identifying IoT malware samples. Building on this idea, Muhammad et al. [16] proposed a lightweight method combining token embedding with a deep classification model. Their technique tokenizes and standardizes packet fields such as timestamps, lengths, and protocol names, yielding significant improvements in real-time classification performance and anomaly detection, especially in resource-constrained IoT environments.

Javaid et al. [17] employed both One-Hot encoding and word embedding for categorical features, such as protocol types and flag statuses, in IoT networks. These representations were input into deep neural networks to detect abnormal traffic. Experimental results demonstrated that embedding semantic information not only improves detection accuracy but also enhances generalization while reducing feature dimensionality.

Collectively, these studies confirm that tokenization strategies are highly effective in the context of IoT anomaly detection. By transforming heterogeneous traffic attributes into unified embedding vectors, such approaches enable models to learn and infer behavioral patterns across both packet-level and application-level traffic. This has significant implications for the scalability and accuracy of intrusion detection systems deployed in diverse and dynamic IoT environments.

Table 2.2 shows the comparison of some features in anomaly detection using Tokenization. For example, Protocol = TCP only retains the field name and value, and directly discards other symbols and spaces.

Table 2.2 Examples of Field-Value Tokenization in IoT Network Traffic

Feature Field	Tokenized Representation
Protocol = TCP	Protocol:TCP
Destination Port = 443	DstPort:443
Source IP = 192.168.0.1	SrcIP:192.168.0.1
Flow Duration = 120000	FlowDuration:120000
Payload Bytes = 56	PayloadBytes:56
Packet Count = 10	PacketCount:10
Flag = ACK	Flag:ACK
Destination IP = 10.0.0.5	DstIP:10.0.0.5

2.3   Hash Embedding in Anomaly Detection

Hash Embedding is a common lightweight feature encoding technology [18], which is particularly suitable for structured, high-dimensional, or large-number-of-categories network data. Its core approach is to convert each field name/field value (or a combination of the two) into a set of indexes through a hash function (such as MurmurHash3), and query the embedding table to obtain a fixed-length semantic vector. The main method is to combine the (field name, field value) of each data sample and pass it through a hash function such as MurmurHash3 to obtain a set of row/col indexes. This set of indices is then used to query a multi-dimensional embedding table, where an initial random, trainable semantic vector is stored at each position [3].

As Gupta and Rakesh et al. [19] proposed a hash embedding-based method for representing protocol-level IoT traffic, especially targeting categorical fields such as destination ports, device types, and payload signatures. Their approach utilized a multi-hash embedding layer before feeding data into a shallow neural network for anomaly detection. Experiments on the IoT dataset showed a 40% reduction in model size while retaining over 97% detection accuracy compared to one-hot encoding.

Feng and Xiaolong et al. had [20] further integrated hash embeddings into a lightweight convolutional architecture for edge-based IoT security. Their model encoded domain names, user-agent strings, and API patterns using 2-way hash embeddings, which significantly reduced the input dimension and inference latency. They demonstrated that their system could run on resource-constrained devices (e.g., Raspberry Pi) with only 30ms per inference, while achieving an F1-score

of 96.5% on the CIC-ToN-IoT dataset.

Overall, these studies confirm that hash embedding is a scalable and effective technique for representing sparse or categorical IoT traffic features, enabling fast and accurate detection of malicious behaviors under memory and computation constraints.

2.4 Multi-Layer Perceptron in Anomaly Detection

Multi-Layer Perceptrons (MLPs) have been widely applied in the field of anomaly detection due to their capability to model non-linear relationships between input features and hidden patterns. Unlike traditional statistical models that rely on predefined thresholds or assumptions about data distribution, MLPs are capable of learning complex, high-dimensional feature representations in a data-driven manner [21].

In recent years, MLP-based anomaly detection methods have been employed in various domains, including network security [22], industrial control systems [23], and IoT environments [24]. These models typically consist of multiple fully connected layers with nonlinear activation functions, such as ReLU or sigmoid, enabling the learning of hierarchical semantic features. The outputs are used to distinguish between normal and abnormal behavior based on reconstruction error, classification scores, or learned distance metrics.

Moustafa and Slay [22] proposed a hybrid intrusion detection system that combines feature selection and deep learning, utilizing a Multilayer Perceptron (MLP) as the final classifier. Experimental results demonstrated that the hybrid approach significantly outperforms classical machine learning algorithms such as Decision Trees and Naive Bayes, achieving over 95% detection accuracy and a low false positive rate, particularly excelling in identifying DoS and probe attacks.

Nguyen et al. [24] developed an anomaly detection method for IoT traffic using an autoencoder framework, with the decoder implemented as a Multilayer Perceptron. They focused on reducing communication overhead while maintaining detection accuracy, suitable for low-bandwidth IoT networks. The model takes raw traffic features (e.g., port numbers, packet sizes) and encodes them into a compact latent space before reconstructing them through a multi-layer MLP. Anomalies are identified based on high reconstruction error. Their experiments on the BoT-

IoT dataset showed that the MLP-based decoder could detect attacks like DDoS and port scanning with an F1-score exceeding 98.5%, while maintaining a false positive rate below 1%, thus demonstrating the effectiveness of MLP in semantic compression and inference within constrained IoT devices.

Nathan Shone and Tran Nguyen Ngoc et al. [25] introduced a hybrid deep learning approach combining a stacked autoencoder with an MLP classifier to detect network intrusions. Their model was evaluated on the NSL-KDD dataset, achieving an accuracy of 85.42% and demonstrating superior performance over classical ML algorithms such as decision trees and SVM.

Similarly, A. H. M. Rahman and B. K. Roy and Chen Li [26] applied a pure MLP-based architecture for anomaly detection in the BoT-IoT dataset. The network consisted of three hidden layers with ReLU activation and dropout regularization. The results showed that MLP achieved over 98.5% detection accuracy and maintained a false positive rate below 1%, outperforming traditional algorithms such as KNN and Naive Bayes.

Ahmad Javaid and Qusay H. Mirza et al. [17] further explored MLP in a deep learning pipeline tailored for IoT environments. They emphasized the importance of feature normalization and used a softmax output layer for multi-class classification. Their experiments on KDDCup'99 and UNSW-NB15 datasets revealed that MLP models trained on optimized features could achieve both high recall and precision in detecting diverse attack types, including DoS, probing, and user-to-root exploits.

These findings suggest that MLP can serve as a strong baseline model in IoT anomaly detection pipelines, especially when combined with proper feature engineering and regularization techniques.

2.5 Semantic Vector in IoT Anomaly Detection

Semantic vector representations, originally popularized in natural language processing (NLP), have gained traction in anomaly detection tasks due to their ability to encode complex contextual information into fixed-length embeddings. In security-related applications, raw network traffic often contains heterogeneous features that lack explicit semantics; transforming these into semantic

vectors enables better generalization and interpretability [27].

Recent works have applied semantic encoding strategies, such as Word2Vec and sequence embeddings, to convert protocol names, IP addresses, or header fields into high-dimensional vectors [14]. These semantic vectors capture latent relationships between fields and behaviors, allowing downstream models to detect subtle deviations from normal patterns. For instance, Shapira et al. [13] proposed Flow2Vec, which encodes sequences of network events into dense vectors, improving anomaly detection in encrypted traffic.

Torres et al. [28] used a self-supervised Transformer model to learn semantic embeddings of packet sequences, tokenized each field and value and converted them into word embeddings, and finally achieved anomaly classification accuracy of over 98% on the $TON_{I}oT dataset$.

Rahman et al. [29] treated DNS/URL traffic as a text sequence, constructed semantic vectors using n-gram segmentation and TF-IDF, and then used SVM and Random Forest for classification, with an F1-score of over 96% for detecting malicious domains.

Nguyen et al. [30] concatenated the structured fields of IoT packets through semantic embedding and entered the AutoEncoder model for reconstruction error analysis. The study pointed out that compared with pure numerical encoding, semantic vectors can effectively improve anomaly recall and precision.

2.6 Mahanobis Distance in IoT Anomaly Detection

Mahalanobis distance was first proposed by Indian statistician Prasanta Chandra Mahalanobis. It proposed a method to measure the "distance" between points and multidimensional statistical distributions, thus breaking through the limitation of Euclidean distance that cannot adjust scale and correlation. Venturini et al. [31] explored the application of Mahalanobis distance in smart home behavior analysis, using multidimensional time series to capture abnormal device usage scenarios. Experiments show that when Mahalanobis distance exceeds the normal threshold, abnormal behaviors such as failures or unexpected operations can be detected. The proposed of following classic formula as below.

$$d_M(\mathbf{x}) = \sqrt{(\mathbf{x} - \boldsymbol{\mu})^T \, \boldsymbol{\Sigma}^{-1} \, (\mathbf{x} - \boldsymbol{\mu})} \qquad (2.1)$$

The equation $d_M(\mathbf{x})$ denotes the Mahalanobis distance, where $\mathbf{x}$ is the observation vector, $\boldsymbol{\mu}$ is the mean vector, and $\boldsymbol{\Sigma}$ is the covariance matrix of the distribution.

Another study examined the applicability of Mahalanobis Distance (MD) in detecting anomalies within IoT network traffic by integrating it with Principal Component Analysis (PCA) for dimensionality reduction [32]. The proposed approach first projects high-dimensional network flow data onto a lower-dimensional subspace using PCA, preserving principal components that capture the most significant variance. Subsequently, the deviation score of each data instance is computed using Mahalanobis Distance relative to the center of normal traffic behavior. The evaluation demonstrates that MD exhibits superior detection performance compared to traditional distance metrics such as Euclidean distance.

Tharewal et al. [10] proposed an intrusion detection method that combines Mahalanobis Distance and cluster analysis to analyze the network behavior patterns of IoT devices. They regarded the multi-dimensional features of packets as sample points, established a distribution model of normal behavior, and calculated the Mahalanobis distance between the test sample and the distribution center to identify anomalies. The research results show that this method can effectively improve the detection rate and low false positive rate.

Kwon et al. [33] proposed an anomaly detection method based on Mahalanobis distance for IoT devices with limited resources. The method calculates the distance between the feature and the normal behavior distribution at the edge device to avoid cloud latency and data leakage risks. Experiments show that the method can quickly and accurately detect abnormal events in smart home and smart factory scenarios.

Chapter 3 Methodology

In this session, we will introduce the S2GE-NIDS (structured semantics and generation embedded network intrusion detection system) architecture and details its operational workflow, clearly delineating each step from semantic tokenization through anomaly detection and decision-making processes.

3.1 Architecture

The architecture of S2GE-NiDS is presented as Figure 3.1 including preprocess model, embedding model, and Mahalanobis model.

Figure 3.1 Architecture of S2GE-NIDS

The further description will begin in the section 3.1.1.

3.1.1 Preprocess Model

In the preprocessing phase, we will do the following process as data file selection and filtering, feature extraction, and tokenization. These steps are designed to transform raw network traffic into structured representations suitable for semantic embedding and anomaly detection.

3.1.1.1 Classify and Clean Data

The first step in the preprocessing pipeline involves selecting and filtering the data files to ensure suitability for subsequent analysis. In this study, network traffic is collected and stored in the Comma-Separated Values (CSV) format a widely adopted and flexible tabular data structure. CSV files are particularly well-suited for structured data representation due to their ease of parsing, compact storage, and seamless integration with mainstream data analysis libraries such as pandas and NumPy in Python. After data format selection, the raw data is merged into a unified DataFrame and subjected to a series of cleaning procedures. At First, all column names are normalized by removing extraneous whitespace and converting naming conventions where necessary to ensure consistency across feature dimensions. Next, Column values containing missing or undefined values are removed to prevent bias in downstream training. Finally, cloumns contain only zeros will be removed. During this stage, the resulting dataset serves as the foundation for the subsequent tokenization and embedding stages.

3.1.1.2 Packet Semantic Extraction

Packet semantic extraction refers to the process of identifying and transforming raw packet-level attributes into semantically meaningful representations that support accurate anomaly detection. As described in Table 2.1, a set of representative features—such as *Destination Port*, *Protocol Type*, *Flow Duration*, *Packet Length*, *Flow Bytes per Second*, *TCP Flag Counts*, and *Connection Count*—have been consistently validated in prior research as effective indicators of anomalous or malicious traffic behaviors.

3.1.1.3 Tokenization ID

Following feature extraction, the next step involves tokenization, where in structured feature fields are transformed into discrete, semantically meaningful string units that can be embedded into vector spaces. Each data instance consists of multiple categorical fields (e.g., `Destination Port`, `Protocol`, `SrcIP`), each encoding specific behavioral traits of network traffic.

Tokenization is performed by concatenating the field name with its corresponding value to

form a unique textual token. For example, a record with values may yield tokens such as *"DestinationPort:80"*, *"FlowDuration:0.32817"*, and *"ProtocolType:TCP"*. These composite tokens act as the atomic semantic units for downstream embedding models (e.g., Word2Vec or contextual encoders), enabling the system to capture field-wise correlations and behavioral semantics. The tokenization format adopted in this study is consistently structured as `<field name>:<field value>`, as illustrated in Table 3.1.

Table 3.1 Example of Tokenized Input Fields

Field Name	Field Value
Destination Port	80
Flow Duration	0.32817
Protocol Type	TCP

3.1.2 Embedding Model

In order to convert network packet features into vector representations that can be processed by the model, this architecture uses an efficient embedded model. The whole process including Hash Embedding, Feature Flattening and Semantic Vector. This section will explain the design principles and processes of each stage in detail.

3.1.2.1 Hash Embedding

Hash embedding is a lightweight vectorization technique that utilizes non-cryptographic hashing to encode tokenized field-value pairs into fixed-size, trainable embeddings [13]. In this study, we adopt the MurmurHash3 algorithm—an efficient and widely used hash function—to map each token to a specific position in the embedding table. Its advantages include fast computation, uniform distribution, and language-independent implementation, whichmakeitwell-suited for scalable anomaly detection in IoT environments [4]. To determine the target index for each token, we apply a modulo operation to the hash value using the smallest three-digit prime number, 233. This approach distributes tokens more evenly within the embeddingspaceandreducescollisionrates. Forexample, thetokengeneratedfromthe field name PORT may yield a MurmurHash3 value of 4283257230. Applying 4283257230 mod 233 results in 56. If the associated port number

(e.g., 405) is similarly hashed and gives a value with mod 233 result of 7, these indices (row 7, column 56) are used to locate the corresponding vector in the embedding table.

Each embedding vector is initially randomized and refined during training. For instance, an example 8-dimensional vector might be: [0.5012, 0.7061, 0.7705, 0.6871, 0.4636, 0.4809, 0.1913, 0.8319]

Table **??** illustrates a subset of the embedding table used in our model. Each row corresponds to a unique index obtained by applying the MurmurHash3 function and modulo operation to a specific token (e.g., Flow Duration_0.32817). The resulting index is used to retrieve an 8-dimensional embedding vector, which captures semantic properties of the original field-value token. These vectors are subsequently concatenated and passed into the MLP encoder to generate a semantic representation.

Table 3.2 Field-Value Hashing and Embedding Vectors

Token	Hash	Modulo (P=223)	Embedding Vector (16-d)
Destination_Port	1172070958	129	[0.5012, 0.7061, 0.7705, 0.6871, 0.4636, 0.4809, 0.1913, 0.8319]

Figure 3.2 FlowChart for Efficiency-based GP

3.1.2.2 Flatten to One Class Vector

Flatten will string the tokenized data into a single vector through the vectors after the embedding column for the next stage preparartion. For example, Destonation Port 80 is [0.5012, 0.7061, 0.7705, 0.6871, 0.4636, 0.4809, 0.1913, 0.8319], Flow Duration 0.32817 is [0.227, 0.9268, 0.676, 0.9304, 0.5891, 0.3531, 0.2451, 0.9082] and Protocol TCP is [0.2309, 0.8674, 0.3565, 0.8259, 0.1846, 0.4375, 0.2524, 0.3008], then the final flatten will be [0.5012, 0.7061, 0.7705, 0.6871, 0.4636, 0.4809, 0.1913, 0.8319, 0.2309, 0.8674, 0.3565, 0.8259, 0.1846, 0.4375, 0.2524, 0.3008, 0.2309, 0.8674, 0.3565, 0.8259, 0.1846, 0.4375, 0.2524, 0.3008]

3.1.2.3 MLP to Vector

In order to integrate the multiple field semantic vectors extracted from the embedding table in each packet into a unified semantic representation, a multi-layer perceptron (MLP) encoder module is introduced here. The main task of this module is to map a flattened one-dimensional vector $\mathbf{x} \in \mathbb{R}^{F \times d}$ to a fixed-dimensional semantic feature vector $\mathbf{z} \in \mathbb{R}^{k}$, where F is the number of fields, d is the embedding dimension of each field, and k is the output vector dimension.

MLP consists of several layers of Fully Connected Layers, each of which combines an activation function with a regularization mechanism. The specific structure is as follows:

- **Input layer**: Input all field vectors as $\mathbf{x} \in \mathbb{R}^{F \times d}$ 。

- **Hidden Layer 1**：

$$\mathbf{h}^{(1)} = \text{Dropout}\left(\text{ReLU}\left(\mathbf{W}^{(1)}\mathbf{x} + \mathbf{b}^{(1)}\right)\right), \quad \mathbf{W}^{(1)} \in \mathbb{R}^{128 \times (F \cdot d)}$$

- **Hidden Layer 2**：

$$\mathbf{h}^{(2)} = \text{BatchNorm}\left(\text{ReLU}\left(\mathbf{W}^{(2)}\mathbf{h}^{(1)} + \mathbf{b}^{(2)}\right)\right), \quad \mathbf{W}^{(2)} \in \mathbb{R}^{64 \times 128}$$

15

- **Hidden Layer 3**：

$$\mathbf{h}^{(3)} = \text{ReLU}\left(\mathbf{W}^{(3)}\mathbf{h}^{(2)} + \mathbf{b}^{(3)}\right), \quad \mathbf{W}^{(3)} \in \mathbb{R}^{32 \times 64}$$

- **Output Layer**：

$$\mathbf{z} = \mathbf{W}^{(4)}\mathbf{h}^{(3)} + \mathbf{b}^{(4)}, \quad \mathbf{W}^{(4)} \in \mathbb{R}^{k \times 32}$$

Each hidden layer uses the ReLU activation function to introduce nonlinear characteristics, which is in the form of:

$$\text{ReLU}(x) = \max(0, x)$$

To prevent overfitting, the Dropout operation is introduced after the first layer. During each forward propagation, some neurons are randomly turned off with a fixed probability p to prevent the model from over-relying on certain features, thereby reducing overfitting and preventing them from participating in the calculation in this round of training. This random deactivation behavior forces the model not to over-rely on certain neurons, thereby improving its generalization ability. During the training phase, some neurons are deactivated with a random probability of $p = 0.2$. The second layer introduces the Batch Normalization operation to accelerate convergence and stabilize training.

Finally output will be $\mathbf{z} \in \mathbb{R}^k$ is the semantic vector of each packet and can be used as the input feature of the anomaly detection or classification module.

3.1.3 Mahalanobis Distance Model

In the final stage of the S2GE-NIDS framework, we apply a statistical distance-based method —**Mahalanobis Distance**—to evaluate whether an observed semantic vector deviates significantly from the expected distribution of normal traffic. This metric is particularly effective for high-dimensional anomaly detection, as it accounts for feature correlations and variance [34].

Let $\mathbf{x} \in \mathbb{R}^n$ denote the semantic vector output from the MLP, and let $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ represent the mean vector and covariance matrix estimated from a subset of benign (normal) training data. The

16

Mahalanobis distance is defined as:

This formulation enables the model to assess how far a sample deviates from the learned semantic center under multivariate normality assumptions. During inference, if $D_M(\mathbf{x})$ exceeds a predefined threshold τ, the corresponding traffic instance is flagged as an anomaly.

We empirically determine τ using the distribution of distances in the training set, often by selecting a percentile threshold (e.g., 95th percentile). This thresholding strategy is advantageous in unsupervised or semi-supervised settings, where labeled anomaly samples may be scarce.

The integration of Mahalanobis scoring into our system introduces the benefits of model interpretability and statistical rigor, effectively enhancing the ability to detect subtle but semantically meaningful deviations in IoT network behavior.

3.1.3.1 Vector-to-Center Comparison

To enhance anomaly detection, S2GE-NIDS introduces a center loss mechanism. During training, all semantic vectors corresponding to "normal" samples are aggregated to calculate a center point c.

- Taking into account the variability and correlation of each feature, the model can more accurately detect abnormal samples that are "off-center".

$$D_M(z) = \sqrt{(z - c)^T \Sigma^{-1} (z - c)} \tag{35}$$

z is the semantic vector of the input sample, c is the center vector of normal samples, and Σ^{-1} is the inverse of the covariance matrix of the training data's embedding vectors.

3.1.3.2 Vector-to-Center Comparison

- The loss is defined as:

$$\mathcal{L} = \frac{1}{N} \sum_{i=1}^{N} \|z_i - c\|^2 = \frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{d} (z_{ij} - c_j)^2 \tag{36}$$

$z_i \in \mathbb{R}^d$ is the embedding vector obtained after the ith input passes through the Semantic Encoder, $c \in \mathbb{R}^d$ is the center point vector during training (center), and N is the total number of samples.

3.1.3.3 Determine the Anomaly Score

After obtaining the semantic vector z of each input data point through the MLP encoder, and computing the center point c based on all normal training samples, the system evaluates how far each sample deviates from the normal data distribution using the Mahalanobis distance metric.

The Mahalanobis distance score $D_M(z)$, as defined in Equation **??**, quantifies the distance between a sample's semantic representation z and the center vector c, while accounting for the variance and covariance of the embedding space. This distance serves as the anomaly score for each sample.

To determine whether a sample is anomalous, we define a threshold τ based on the distribution of distances observed in the training data. A sample is classified as anomalous if its Mahalanobis distance exceeds this threshold:

$$\text{Anomaly}(z) = \begin{cases} 1 & \text{if } D_M(z) > \tau \\ 0 & \text{otherwise} \end{cases} \tag{36}$$

Here, τ can be determined in several ways, such as:

- Using the mean plus k standard deviations from the training distribution (e.g., $\tau = \mu + k\sigma$).

- Setting τ based on a desired false-positive rate (e.g., the 95th percentile of $D_M(z)$ on normal samples).

This threshold-based mechanism enables the system to make binary decisions (normal vs. anomalous) while preserving the interpretability and statistical grounding of the anomaly scores.

3.2　Flow

This section presents the proposed system, detailing its operational principles, and experiment step. The complete flow consists including Preprocess Model, Embedding Model and Mahalanobis Distance.

3.2.1　Preprocess Model

As shown in the figure 3.3, the system receives the uploaded network packet data and checks whether its format conforms to the CSV (comma separated value) format. If the data format does not conform to the CSV format, the system will not take action. In the next stage, the system will clean up the data fields, including removing any missing or special characters in the data package.
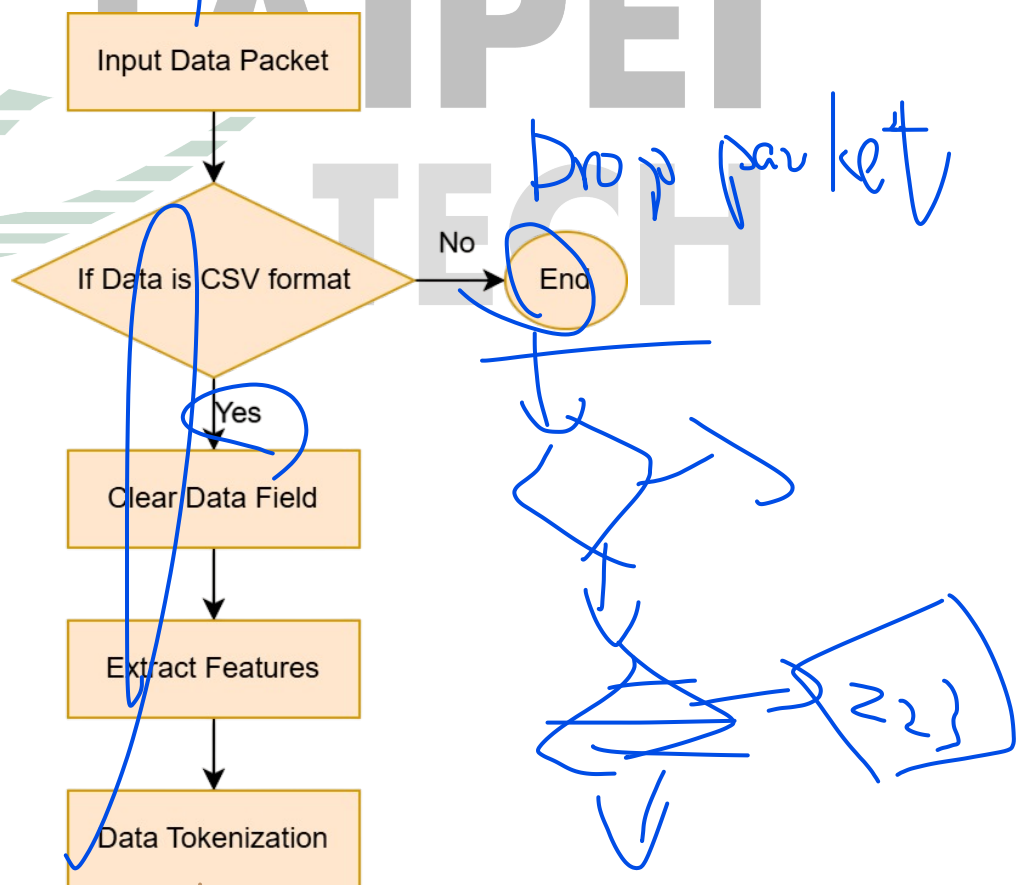

Figure 3.3 Flow Chart for Preprocess Model

Subsequently, specific fields related to common anomaly detection features are extracted, such as Destination Port, Protocol Type, and Source IP (SrcIP). These fields serve as important

inputs for subsequent model analysis.

Finally, the field names and their respective values are combined into tokens—for instance, `Protocol_TCP` or `Port_80`—and fed into a semantic embedding model to be transformed into vectors for further processing.

3.2.2 Implementation Procedure

This module is responsible for converting the structured semantic token sequence produced in the pre-processing stage into a fixed-dimensional numerical vector representation. This module is including Hash Embedding, Flatten to One Class Vector and MLP to Vector.
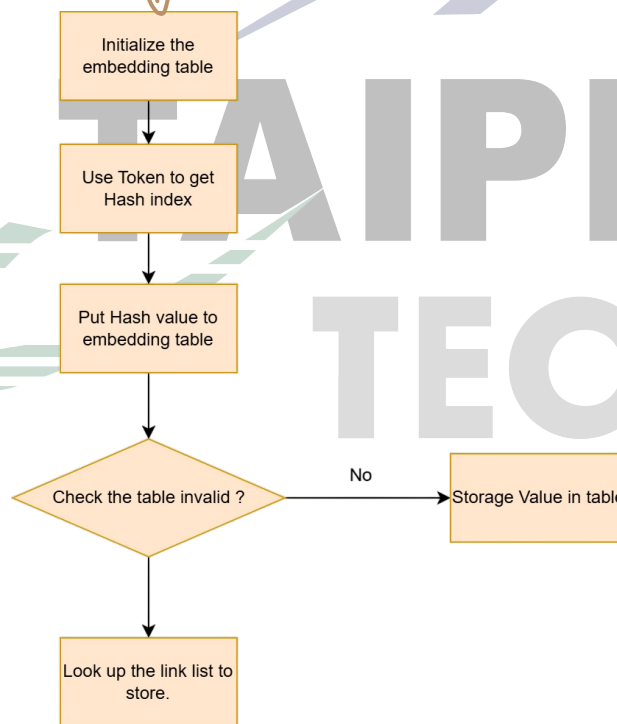

Figure 3.4 Hash Embedding for Embedding Model

Traditional one-hot or dictionary embedding methods require maintaining a vocabulary, which is not efficient in IoT packets. Therefore, this study uses the non-encrypted hash function MurmurHash3 to map each <field name>:<value> token to a trainable embedding position.

To map discrete feature tokens into a fixed-size embedding space without maintaining a pre-defined vocabulary, we employ a dual-stage hash embedding strategy. Each token in the form of `<FieldName>:<Value>` is decomposed into two components: the field identifier and the as-

sociated value. Both components are independently passed through the non-cryptographic hash function MurmurHash3, which offers fast computation and near-uniform distribution.

Formally, for a given token $t = \texttt{Field:Value}$, we compute:

$$\text{row\_idx} = \text{MurmurHash3}(\texttt{Field}) \bmod P \qquad (3.1)$$

$$\text{col\_idx} = \text{MurmurHash3}(\texttt{Value}) \bmod P \qquad (3.2)$$

where $P = 233$ is a small prime number chosen to reduce the probability of hash collisions and to ensure efficient modular indexing.

The resulting $(\text{row\_idx}, \text{col\_idx})$ pair identifies a unique coordinate in the 2D embedding table $\mathbf{E} \in \mathbb{R}^{P \times P \times d}$, where each entry holds a trainable d-dimensional embedding vector.

3.2.3 Mahalanobis Distance Model

In this section we use the anomaly detection method based on Mahalanobis distance as the core model for determining. We will introduce Vector-to-Center Comparison, Vector-to-Center Comparison and Determine the Anomaly Score.

Given N semantic vectors $\mathbf{z}_1, \ldots, \mathbf{z}_N$ generated from benign training data, we first compute the statistical mean (center) vector $\boldsymbol{c}$ and covariance matrix $\boldsymbol{\Sigma}$:

$$\boldsymbol{c} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{z}_i \qquad (3.3)$$

$$\boldsymbol{\Sigma} = \frac{1}{N-1} \sum_{i=1}^{N} (\mathbf{z}_i - \boldsymbol{c})(\mathbf{z}_i - \boldsymbol{c})^T \qquad (3.4)$$

For any test vector $\mathbf{z}$, the Mahalanobis distance $D_M(\mathbf{z})$ from the normal distribution is calculated as:

$$D_M(\mathbf{z}) = \sqrt{(\mathbf{z} - \boldsymbol{c})^T \boldsymbol{\Sigma}^{-1} (\mathbf{z} - \boldsymbol{c})} \qquad (3.5)$$

A larger distance indicates a greater deviation from the normal behavior, suggesting a higher probability of being anomalous.

We define a threshold τ based on the distribution of $D_M(\cdot)$ in the training data (e.g., 95th percentile). A test vector $\mathbf{z}$ is labeled as anomalous if its distance exceeds τ:

$$\text{Anomaly}(\mathbf{z}) = \begin{cases} 1, & \text{if } D_M(\mathbf{z}) > \tau \\ 0, & \text{otherwise} \end{cases} \tag{3.6}$$

- **Input**: Semantic vector $\mathbf{z} \in \mathbb{R}^k$ (from MLP)

- **Output**: Anomaly score $D_M(\mathbf{z})$ and binary decision

- **Computation**: Based on c and Σ estimated from training data

- **Unsupervised**: Requires only benign data for training

- **Interpretable**: Outputs a clear statistical distance as anomaly score

- **Statistically Sound**: Incorporates feature correlation via covariance

- **Efficient**: Only requires mean and covariance estimation once during training

Chapter 4 Implementation

The experimental implementation of this study was conducted on the Windows 11 operating system. Visual Studio Code (VS Code) was utilized as the primary development environment, integrated with the Anaconda distribution for Python to manage package dependencies and virtual environments. A range of scientific computing and machine learning packages were installed to facilitate algorithm development, model training, and evaluation workflows. Detailed configuration steps and setup instructions are described in the following subsection.

4.1 Hardware Requirements

Table 4.1 provides detailed specifications and purposes of each hardware component utilized in our experimental environment.

Table 4.1 Hardware Requirements

Component	Specification
CPU	12th Gen Intel(R) Core(TM) i5-12500H @ 2.50 GHz
RAM	16.0 GB (15.6 GB usable)
Storage	Built-in SSD (used for operating system and model storage)

4.1.1 Software Requirements

This chapter mainly introduces the software installation process, which is divided into several steps. Table 4.2 lists the software used in our experimental setup, along with their purposes and license types.

Step 1: Installing Anaconda

Anaconda is an open source Python platform designed for data science and machine learning development, integrating the most commonly used data analysis tools and libraries. It has a rich built-in data science suite, including core tools such as Numpy (numerical operations), Pandas (data processing), and Seaborn (data visualization).[1]

---

[1]https://www.anaconda.com/products/distribution

Table 4.2 Software and Libraries Used in the Experiment

Software/Library	Version	Purpose	License
Visual Studio Code [37]	1.89.1	A lightweight and extensible code editor used as the primary integrated development environment (IDE) for editing Python scripts and managing project structure.	MIT
Anaconda Prompt [38]	2024.02	A command-line interface provided by the Anaconda distribution, used for managing Python virtual environments and installing dependencies via Conda or pip.	BSD
Python [39]	3.9.18	The main programming language used to implement the core modules of the proposed system, including preprocessing, model training, and evaluation routines.	Python License
NumPy [40]	1.26.4	Provides high-performance array structures and functions for numerical computing, especially efficient vector and matrix operations.	BSD
Pandas [41]	2.2.2	Offers powerful data manipulation and analysis tools, including DataFrame structures used for preprocessing and filtering packet data.	BSD
Scikit-learn [42]	1.4.2	Provides a wide range of machine learning algorithms, particularly the Multi-Layer Perceptron (MLP) classifier used in this study.	BSD
mmh3 [43]	4.0.1	Implements MurmurHash3, a fast non-cryptographic hashing function used to convert tokens into integer values for embedding.	MIT
PyTorch [44]	2.2.2+cpu	A deep learning framework used to define and train neural networks, including custom embedding and classification models.	BSD

Go to the official Anaconda website (figure 4.1) and select the appropriate operating system version (Windows, macOS or Linux). According to the system recommendations of your computer, choose the 64-bit version for better performance.

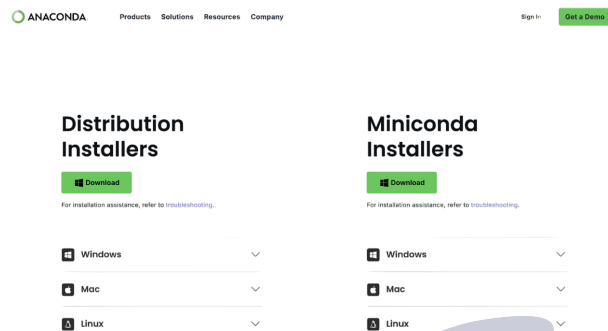

Figure 4.1 Download on Official Anaconda Website

Install Anaconda Double-click the downloaded Anaconda installation file (installer) to start the installation program. And click "Next" to proceed to the next step (4.2). Select the installation type. If it is for personal use only, it is recommended to select "Just Me", then click "Next".

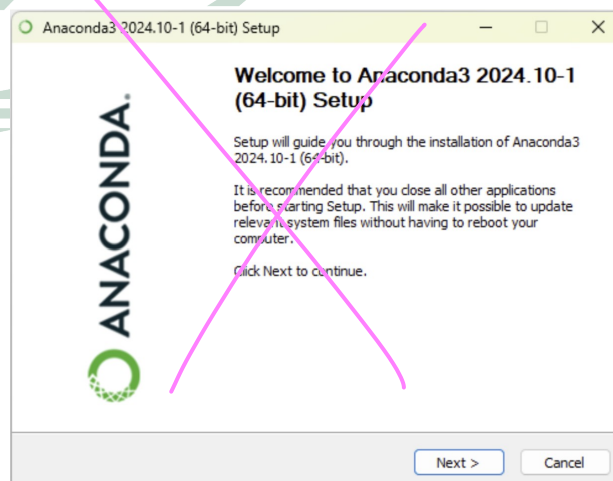

Figure 4.2 Installation for Anaconda

In the installation options, it is recommended not to check Add Anaconda to the PATH environment variable (unless there are special requirements), and directly click "Install" to start the installation.

Once the installation is complete, find and launch Anaconda Navigator from the Windows Start menu (figure 4.3).

**Step 2: Installing Visual Studio Code**

Figure 4.3 FlowChart for Preprocess Model

Visual Studio Code (VS Code) (figure 4.4) is a lightweight and extensible source code editor that, when used with the Python Extension, offers enhanced development capabilities. The installation package can be obtained from the official website[2].

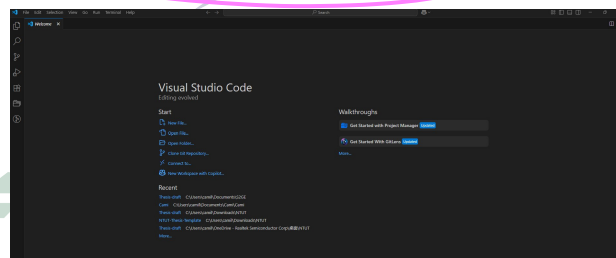

Figure 4.4 Visual Studio Code

Step 3: Creating a Python Virtual Environment

Use the Anaconda Prompt to create a virtual environment with the designated Python version:

```
conda create -n nids_env python=3.9
conda activate nids_env
```

Step 4: Installing Required Packages

The packages required in this study are listed below and can be installed using pip:

```
pip install numpy pandas scikit-learn matplotlib seaborn torch mmh3
```

A brief description of each package is provided in Table 4.2.

---

[2]https://code.visualstudio.com/

Step 5: Selecting the VS Code Interpreter

In Visual Studio Code, press `Ctrl+Shift+P` to open the command palette, then select *"Python: Select Interpreter"*. Choose the previously created `nids_env` virtual environment from the list of available interpreters.

4.1.2 Verifying the Installation

To verify the installation, create a file named `main.py` and include the following test code:

```python
import numpy as np
import pandas as pd
import torch
import mmh3
print("All packages loaded successfully!")
```

Execute the script in the terminal with the following command:

```
python main.py
```

4.1.3 Dataset Description

本研究使用公開可得的 **CICIoT2023** 的資料集進行實驗。該資料集包含各種 IoT 網路設備之正常與異常流量封包,經由 Wireshark 擷取並轉換為 .csv 格式。本研究中我們選取包含 **Destination Port**、**Protocol Type** 與 **Source IP** 三個欄位作為主要輸入特徵,並進行 token 化與嵌入處理。

其中,訓練資料包含 $N = 15,000$ 筆正常封包樣本,測試資料包含 $M = 5,000$ 筆異常樣本與 $3,000$ 筆正常樣本,混合後進行無監督異常偵測評估。

If the message is displayed successfully, it indicates that the environment has been set up correctly.

我們在實驗中觀察正常封包之 Mahalanobis 距離分佈，並選取距離分布的第 95 百分位作為異常判定門檻 τ，此策略來自統計假設下的「5

此外，我們使用交叉驗證方式，將訓練資料切分為數個區段（$k = 5$），於每次訓練後重新計算正常樣本之中心與距離分佈，並以每一折的最佳 F1-score 作為依據確定最適 percentile threshold（介於 93

Chapter 5 Results

Table 5.1 Anomaly Detection Performance Comparison

Model	Precision	Recall	F1-Score	Time (ms/sample)
Isolation Forest	0.82	0.78	0.80	1.2
AutoEncoder	0.85	0.83	0.84	2.5
S2GE-NIDS	**0.86**	**0.90**	**0.88**	**0.8**
